DISCRETE-VARIABLE EXTREMUM PROBLEMS

GEORGE B DANTZIG

The Rand Corporation, Santa Monica, California

This paper reviews some recent successes in the use of linear programming methods for the solution of discrete-variable extremum problems. One example of the use of the multistage approach of dynamic programming for this purpose is also discussed

NUMBER of important scheduling problems, such as the assignment of flights for an airline or the arrangement of stations on an assembly line, require the study of an astronomical number of arrangements in order to determine which one is 'best' The mathematical problem is to find some short-cut way of getting this best assignment without going through all the combinations By allowing the unknown assignments to vary continuously over some range, mathematicians often arrive at pseudo solutions in which one or more assignments turn out to be fractions instead of whole It is common practice to adjust such values to whole numbers Since mathematical models are often imperfect mirrors of reality, this approach is recommended for most practical problems. But since such procedures can occasionally give an answer far from the best, mathematicians have been working on improved techniques. The purpose of the present paper is to review some recent successes using linear programming methods in this difficult area. A thorough discussion of the multistage approach of dynamic programming is beyond the scope of this paper, one example is presented, however, in which this method provides an efficient algorithm

To be more explicit, there are certain classes of problems that are combinatorial in nature and easy to formulate, but that mathematicians have had only partial success in solving. These arise often in the form of discrete-variable programming problems, such as

- 1 The empty-containers problem
- 2. The multistage machine-scheduling problem [1]
- 3. The flight-scheduling problem [2]
- 4. The fixed-charge problem [3]
- 5. The traveling-salesman problem [4]

Examples of problems that have yielded to analysis are the following

- 6. The assignment problem [5 6]
- 7. The problem of the shortest route in a network
- 8. The tanker-scheduling problem [7]

The purpose of this paper is to outline an approach that, we believe, has a high probability of verifying whether or not, in any particular nu-

merical case, an optimum combination has been selected The human mind seems to have a remarkable facility for scanning many combinations and arriving at what appears to be either a best one or a very good one The actual number of combinations can be extremely large, however, making it almost impossible in many cases to verify that the choice is, indeed, a good one Any ideas, therefore, that can help to verify that a conjectured solution is optimal should be of interest

The technique presented here is not foolproof and cannot be guaranteed to work in all cases But it is an approach that several people at Rand have found to work in each numerical case considered Harry Markowitz and Alan Manne have used it, for example, on flight-scheduling problems, and the present author has employed it with Selmer Johnson on various scheduling and container problems and with RAY FULKERSON and SELMER Johnson in our article on the traveling-salesman problem

THE MARRIAGE PROBLEM

To illustrate many of the concepts of this paper, we begin by describing the assignment problem in a popular form. Imagine that a group of hearty pioneer bachelors have gone on ahead of the womenfolk to form a The prospective brides, who have not met the future grooms, now arrive, and after a short courtship in which the boys and girls get acquainted with one another, it is decided to have a ceremony and get things over with In order to decide who marries whom, the prospective brides rank the various boys in order of preference Based on their ratings, the selections are to be made Of course, if each girl were to choose a different boy for top rating there would be no problem, it is only when more than one girl has her eye on one particular boy that the selection problem becomes interesting

From a mathematical point of view, let a variable $x_{ij}=1$ mean that the 1th bride (in the solution to the problem) marries the 1th boy, and let $x_{ij} = 0$ mean that she does not Then we have certain equations that have to be satisfied

$$\sum_{j=1}^{n} x_{i,j} = 1, \qquad (i = 1, 2, \dots, n)$$

$$\sum_{j=1}^{n} x_{i,j} = 1 \qquad (j = 1, 2, \dots, n)$$

$$\sum_{i=1}^{n} x_i = 1 \qquad (j=1,2, n)$$

The equations of the first set state that each bride marries just one boy Similarly, the equations of the second set state that each boy marries just one girl Moreover, by explicitly stating that $x_{ij} = 0$ or 1, we require a solution that does not admit fractional solutions, in other words, bigamous and, generally, polygamous solutions are ruled out

Now let d_{ij} be the rank given by the *i*th girl to the *j*th boy

To determine the 'best' over-all selection, the x_i , are to be selected to satisfy the foregoing equations and, subject to these constraints, are to minimize the form

$$\sum_{i,j} d_{i,j} x_{i,j} = z$$

The rating factor d_{ij} , better known as the 'disappointment' factor, measures the degree of disappointment if the *i*th bride happens to get the *j*th boy Hence, as here defined, a best selection is one that minimizes the total disappointment

THE STANDARD DISCRETE FORM

To generalize, the problems we are considering belong to the class of extremizing problems of linear programming in which, for given constants $a_{i,j}$, $b_{i,j}$, and $c_{j,j}$ ($i=1, 2, \ldots, m, j=1, 2, \ldots, n$), values x_1, x_2, \ldots, x_n are to be determined, subject to the constraints

$$\sum_{j=1}^{j=n} a_{ij}x_{j} = b_{i}, \quad (x_{j} \ge 0, i = 1, 2, \dots, m) \quad (1)$$

in such a way as to minimize the linear form

$$\sum_{j=1}^{j=n} c_j x_j = z, \tag{2}$$

but for us the variables x, are further constrained to satisfy

$$x_{j} = 0 \text{ or } 1 \tag{3}$$

For a programming problem to be discrete, it is not necessary that the variables be 0 or 1. In flight-scheduling problems, for example, the variables that represent the number of flights are required to be nonnegative integers. There exists, however, a very simple device by which such problems can be reduced to the 0-or-1 form if the variables have known upper bounds. Indeed, let x be a variable that can take on only nonnegative integral values and let the integer k be an upper bound for x, so that $x \le k$, then x can be replaced by the sum

$$y_1 + y_2 + y_k$$
 $(y_1 = 0 \text{ or } 1)$

For this reason the representation (1), (2), and (3) of a discrete programming problem shall be referred to as the standard discrete form

An important property of any set of points whose coordinates satisfy equation (3) is that the points form the vertices of a convex polyhedral set in the *n*-dimensional space (x_1, x_2, \dots, x_n) This is perhaps intuitively obvious since a point such as $(0, 1, 0, \dots, 0, \dots, 1)$ is one of the vertices of the unit *n* cube (which of course is convex). It is well known that in linear programming problems an optimal solution exists that is an extreme

point of feasible solutions This suggests that in seeking a solution to the standard discrete problem we first weaken the hypothesis as follows

replace
$$x_j = 0$$
 or $x_j = 1$ by $0 \le x_j \le 1$
Continuous range (4)

Since the replacement given in (4) is less restrictive than the condition (3), it follows that the set of solutions to the linear programming problem (1) and (4) forms a convex polyhedral set C that contains the convex polyhedral set C^* whose vertices are the solutions of (1) and (3) It is easy to see, however, that every extreme point (vertex) of C^* is an extreme point of C (see open dots in Fig. 1), but there may be extreme points of C (see

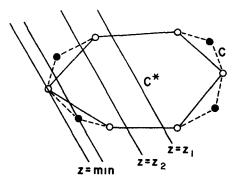

Fig. 1. Schematic representation (2-dimensional case) of the convex polyhedral set C^* whose vertices are the solutions of a discrete linear-programming problem, and of the convex polyhedral set C of solutions of the corresponding continuous problem

closed dots in Fig. 1) that are outside of C^* The parallel lines in Fig. 1 represent different positions of the hyperplane

$$c_1x_1+c_2x_2+c_nx_n=z=\text{constant},$$

and it is clear that, depending on the values of the c_1 , an extreme point corresponding to z=minimum may belong to C^* (as in Fig. 1) or may belong to C and not to C^*

A remarkable property of the 'assignment' problem (and the same holds true for the 'shortest-route' problem, which we shall describe in a moment, and of the tanker-scheduling problem) is that

$$C^* = C \tag{5}$$

Indeed, this result holds true for a general class of 'transportation' problems of which these are special cases Thus, in the marriage problem, when we replace the condition $x_{i,j}=0$ or 1 by $0 \le x_{i,j} \le 1$, we are, in effect, allowing

the class of possible solutions to be extended from the monogamous to the polygamous situation in which sharing of mates is possible. The fact that $C^* = C$ states that monogamy will turn out to be the best of all relations in the sense that it will minimize over-all 'disappointment' as defined above †

THE SHORTEST-ROUTE PROBLEM

Now a second example that has this fundamental property—namely, that the extreme points of the continuous version of the programming problem are the same as those of the discrete form—is the 'shortest-route problem' Let us suppose there is a package originating in Los Angeles that is to be delivered to Boston along one of the different routes shown in Fig 2, where the lengths d_i , of various links of the transportation network are as shown—We are interested in having the package delivered over the shortest route—The package is allowed to be shipped from city to city

† At the summer, 1955, meeting of ORSA at Los Angeles where this paper was first presented, I (the author) was interviewed by the press, and the following event took place. The reporter turned out to be the brother of my little girl's piano teacher, and so we became quite chummy. I explained to him that linear programming models originated in the Air Force and I described the uses of linear programming in industry. It became obvious that this veteran Hollywood reporter was having a hard time seeing how to make the material into exciting news copy. In desperation I suggested, "How about something with sex appeal?" "Now you're talking," he said "Well," I continued, "an interesting by-product of our work with linear programming models is a proof—perhaps the first mathematical proof in history—that of all the forms of marriage (monogamy, bigamy, polygamy), monogamy is the best of all possible relations?" he queried "Yes," I replied "Man," he said, shaking his head in the negative, "you've been working with the wrong kind of models"

Aside from using an anecdote to interpret fractional solutions, a serious reader may wonder whether the above may be construed as a "proof" of the superiority of one of the accepted mores of Western civilization. Polygamy, it should be pointed out, usually means several sives for one man. Thus, contrary to our assumptions, the sum of the variables associated with a man could exceed unity while that of a woman could be zero or one. Our model is entirely inadequate under this condition for establishing such a proof

However, in another sense it may have more validity In our civilization divorce is commonplace Hence, fractions may be interpreted as the proportion of a person's life spent with one mate or another Here the only essential assumption is that the rating factors depend on the pairings, and the total is the weighted sum of the individual ratings. This contains the implicit assumption that the over-all rating is the same whether a person married A first and B later or the other way around It also assumes that the over-all rating for being married at different times to A, B, and C is the weighted average of the individual ratings for A, B, and C To be realistic, the model should be extended to include a state of being single, along with its corresponding rating This is easily done. Under this extension, and under the stated assumption, the general conclusion is that an optimum marriage pattern for a group of n men and n women exists that is free from divorce Thus there is an assignment, where each individual remains married to just one person (or remains single) throughout his adult life, that is better (or at least not worse) over-all than any assignment involving divorce This result is quite apart from the adverse effect of divorce on children

along the lines of the network until it arrives at Boston For $i \neq j$, let $x_{i,j}=1$ mean that the package is shipped directly from city i to city j, and let $x_{i,j}=0$ mean it is not Let $x_{i,i}$ be the total quantity shipped into the city i, which we require to be the same as the total quantity shipped out

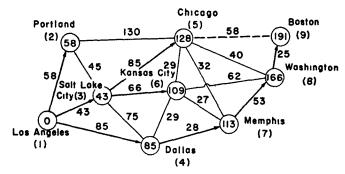

Fig 2 Illustration of the shortest-route problem

This situation gives rise to a system of constraints on the variables very similar to the system for the assignment problem, namely, we have •

The first equation in (6) states that the amount shipped out of Los Angeles is unity. The last equation in (7) states that the amount shipped into Boston is unity. Equating the x_n in the *i*th equation of (6) with the x_n in the (i-1)st equation of (7) yields the assertion that the amount shipped out equals the amount shipped in for each intermediate city, $i=2,3,\ldots,n-1$

Subject to the constraints (6) and (7), and to the further constraint that $x_{i,j}=0$ or 1 for $i\neq j$, we are to minimize the form

$$\sum_{i=1}^{n} \sum_{j=1}^{n} d_{ij} x_{ij} = z, \qquad (n=9) \quad (8)$$

that is, we are to minimize the total distance that the package travels

Thus, the shortest-route problem is very similar to the marriage problem. Now if, in the shortest-route problem, we replace the condition $x_{i,j}=0$ or 1 by $0 \le x_{i,j} \le 1$, it is again true that $C^*=C$, and accordingly this problem also can be solved by standard linear programming techniques A simple graphical procedure for this will now be described

First of all, draw a tree in the network shown in Fig 2. By drawing a tree is meant the following. Start from Los Angeles and draw some route conjectured to be optional—for example, a route across the Southern states and then up along the East Coast. Draw arrows indicating this route, then fan out from cities along this route to other cities, drawing more arrows. Repeat until each city in the network is reached either directly or indirectly from Los Angeles. Be sure that the links associated with the arrows do not form loops. An example of a tree is shown by the heavy arrows in Fig 2. Each such tree corresponds to a basis in the simplex method, and the so-called prices (which are analogous to Lagrange multipliers) are computed in the following manner.

At city i put a number u_i which constitutes the distance from Los Angeles if we go along the routes formed by the tree For example, from Los Angeles to Memphis, city (7), the distance is 85 plus 28, hence $u_7 = 113$ (circled entry at Memphis) Similarly, from Los Angeles to Kansas City along the tree is 43 plus 66, which gives 109, and so forth The next step is to test whether the tree and route in the tree from Los Angeles to Boston is a solution to the 'shortest-route problem'. To do this, we must determine whether the circled numbers are actually the shortest-route distances from Los Angeles when compared with other routes in the network they are, we have an optimal solution To test whether these are minimum distances for each directed link of the network, joining city i to city j, we compare the distance d_{ij} , with $u_{ij}-u_{ij}$. If for all directed links we have $u_1 - u_2 \le d_{12}$, then the routes along the tree are the shortest distances from Los Angeles to any other city If not, the solution can be improved Consider, for example, the Chicago-Boston link Here $u_9 - u_5 = 63$ and $d_{5,9} = 58$, so that $u_9 - u_5 > d_5$, and the tree shown in Fig. 2 is not optimal. Indeed, for a route going along the branches, the total distance to Boston is 191 However, if it went via Chicago, and then to Boston, it would be 128 plus 58, which is 186, this is 5 units less. In this case we could get a better solution by inserting an arrow between Chicago and Boston, recording 186 at Boston, and removing the arrow between Washington and Boston Again, we could test whether the 128 at Chicago could be improved by noting whether a shorter route could be obtained, by considering the Portland-Chicago link. However, here 58 plus 130 is not less than 128, so we try the Kansas City-Chicago link But here again 109 plus 29 is not less than 128 By continuing in this manner, we can eventually arrive

at a situation where it is not possible to find any directed link that leads to an improvement of the distance shown in any circle. If so, we have arrived at an optimal solution. For the example at hand, the optimal tree is the same as that shown in Fig. 2, except that the arrow from Washington to Boston is dropped and one from Chicago to Boston is inserted. The 191 at Boston is changed to 186. The values of the x_i , are unity along the path in the final tree from Los Angeles to Boston and are zero elsewhere. Hence the optimal path is from Los Angeles to Salt Lake City, then to Chicago, and finally to Boston.

THE KNAPSACK PROBLEM

In certain types of problems, we can get extreme-point solutions for which not all the values of the x_i , are either zero or one. When any of the x_i , have fractional values, the corresponding extreme points are referred to as fractional extreme points. Now an example of this occurs in the knapsack problem. In this problem a person is planning a hike and has decided not to carry more than 70 lb of different items, such as bed roll, geiger counters (these days), cans of food, etc

We try to formulate this in mathematical terms Let a, be the weight of the jth object and let b, be its relative value determined by the hiker in comparison with the values of the other objects he would like to have on his trip Let x,=1 mean that the jth item is selected, and x,=0 mean that it is not selected We express the weight limitation by

$$\sum_{j=1}^{j=n} a_j x_j \le 70, \tag{9}$$

with

$$x_{j} = 0 \text{ or } 1,$$
 (10)

and wish to choose the x, so that the total value

$$\sum_{j=1}^{j=n} b_j x_j = z \tag{11}$$

is a maximum

Now we can show this pictorially in the plane (Fig 3) if one coordinate axis measures weight a and the other measures value b. Each object then is represented by a point having coordinates (a_j, b_j) . The problem, graphically, is to select a subset of these points that represents the set of items that he carries with him on his hike, the others he rejects. Let us see what type of graphical solution is obtained if the condition $x_j=0$ or 1 is replaced by the condition that the variables can be anywhere in the interval from 0 to 1. Then the problem can be solved by regular linear programming methods, indeed, because of its very simple form it admits an immediate solution. Rotate clockwise a ray with the origin as pivot point

and b axis as starting position. Items corresponding to points swept out by the ray are selected in turn until the sum of their weights exceeds the weight limitation. If for the jth item the weight limitation would first be exceeded, the value x_j is chosen as that fractional part of its weight a_j , that would make the sum come exactly to 70 lb. With the exception of this one item all the items swept out by the ray have the value $x_j = 1$, while those not swept out have the value $x_j = 0$. It will be noted that this is

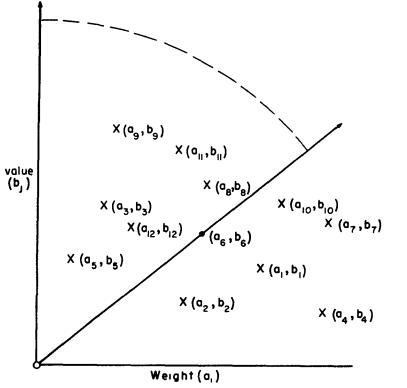

Fig 3 Graphical solution of the knapsack problem

very close to the kind of solution desired All the x_i 's are either 0 or 1 with the exception of the one that has a fractional value

Now at this point the question is natural, "What happens if the solution is rounded?" The effect of rounding up or down is of course to change the total weight carried to a number different from 70 lb. If the model is imperfect—in other words, if the hiker does not really mean exactly 70 lb—this may be a satisfactory way of getting rid of the fractional solution, this is particularly true if the weight of individual items is small relative to 70 lb. For most practical problems, the rounding procedure is probably

all that is needed Our object here, however, is to explore ways of getting an exact mathematical solution

The first of these is due to R Bellman, [8] and is straightforward, it uses the functional-equation approach of dynamic programming. It is recommended where there are only a few items and only one kind of limita-Extensions to two or more limitations—say one on total weight and another on total volume—can be done, but there would be a considerable increase in the amount of computational work. The method consists in ordering the items in any arbitrary way and determining what items would , or 70, and (b) the be carried if (a) the weight limitation were w=1, 2,selections were restricted to only the first k items. For example, if k=1and $w < a_1$ (where a_1 is the weight of the first item) then the item would not be selected, but if $w \ge a_1$, it would be From this it is easy to decide, for every total weight w=1, 2,, 70, what the selections would be for the first two items (k=2), and thence inductively for k=3, 4, $, n \quad \text{Indeed}.$ suppose we wish to determine whether we select the (k+1)st item if our weight limitation is w when we know how to make the selections for the first k items for any weight w=1, 2,, 70

Let $F_k(w)$ be the highest total value that can be obtained with the first k objects under weight limitation w. Then, under the same weight limitation w, the highest total value that can be obtained with first k+1 objects is $F_k(w)$ if the (k+1)st object is not selected, but is $b_{k+1}+f_k(w-a_{k+1})$ if the (k+1)st object is selected. Hence, the (k+1)st object is or is not selected depending on which of these is higher. Thus not only is the selection for k+1 objects determined, but it also is clear that $F_{k+1}(w)$ is given for $w \ge a_{k+1}$ by

$$F_{k+1}(w) = \max[F_k(w), b_{k+1} + F_k(w - a_{k+1})]$$
(12)

and $F_{k+1}(w) = F_k(w)$ for $w < a_{k+1}$ The procedure is iterated for each w and repeated for $k = 1, 2, \dots, n$

The linear programming approach consists in putting such additional linear-inequality constraints on the system that the fractional extreme points of C where the total value z is maximized will be excluded, while the set of extreme points of the convex hull C^* of admissible solutions will be unaltered. The procedure would be straightforward except that the rules for generating the *complete* set of the additional constraints is not known. For practical problems, however, rules for generating a partial set of constraints is often sufficient to yield the required solution.

Let us suppose, as in Fig. 3, that the ray swept out items 5, 3, 12, 11, 8, and 9 before the weight limitation was reached, but that when it reached item 6 the weight limitation was exceeded, so that

$$a_5 + a_3 + a_{12} + a_{11} + a_8 + a_9 < 70,$$

$$a_5 + a_3 + a_{12} + a_{11} + a_8 + a_9 + a_6 > 70$$

We wish to exclude the fractional extreme-point solution

$$x_{5} = x_{3} = x_{12} = x_{11} = x_{8} = x_{9} = 1$$
 for $0 < x_{5} < 1$,
 $x_{j} = 0$ for all other j

It is clear that for an admissible solution not all $x_j=1$ for the seven points j=5, 3, 12, 11, 8, 9, 6, for otherwise the weight limitation would be violated. This means that the sum of these variables cannot exceed 6, or

$$x_5 + x_3 + x_{12} + x_{11} + x_8 + x_9 + x_6 \le 6 \tag{14}$$

Since the fractional extreme-point solution (13) does not satisfy this constraint, it is clear that the effect of adding the particular inequality (14) is to exclude this fractional extreme point. Form (11) is maximized under conditions (9) and $0 \le x, \le 1$, but with the constraint (14) added. Again a new fractional extreme point may turn up for the new convex C, and it will be necessary again to seek a condition that will exclude it. For the most part the conditions added will be other partial sums of the x, similar to (14). However, at times more subtle relations will be required until at last an extreme point is obtained that is admissible

Since the discovery of these more subtle relations is more an art than a science, the reader may dismiss the whole approach as worthless. However, experiments with many problems by the author and others indicate that very often a practical problem can be solved using only such obvious supplementary conditions as (14). In an experiment with a number of randomly chosen traveling-salesman problems involving nine cities, simple upper bounds and so-called simple 'loop conditions' on the variables were sufficient to yield the desired discrete solution. This indicates that the probability of need of the more subtle constraints is low in any given problem. To appreciate the power of this procedure it should be noted that for each nine-city case solved the tour that minimized the total distance covered was one from among 362,880 ways of touring nine cities and was selected in about two hours of hand-computation time

DYNAMIC PROGRAMMING AND THE NUMERICAL SOLUTION OF VARIATIONAL PROBLEMS

RICHARD BELLMAN

The Rand Corporation, Santa Monica, California

THE PURPOSE of this paper is to illustrate the application of the theory of dynamic programming to the numerical solution of a large class of variational problems of the type occurring in a variety of applications. Many of these problems either escape in entirety the techniques of the classical calculus of variations, or else can be treated only with the aid of quite detailed and complicated analysis.

Although the methods we shall employ are equally suited to treat the problem of determining the analytic structure of the solution, in this paper we shall focus exclusively upon computational techniques

Our aim is to present a simple, readily applicable technique, requiring no mathematical background beyond elementary calculus, which can be used to compute the solution of a variety of problems in a routine fashion, with no regard to linear or nonlinear, stochastic or deterministic features of the underlying processes

REPRESENTATIVE PROBLEMS

LET US begin by describing a number of representative variational problems arising in various branches of economic, industrial, and engineering study, and then point out the difficulties of these problems, as far as conventional treatment is concerned

4. A Classical Variational Problem

Consider the problem of determining the minimum of the functional

$$J(x) = \int_0^T F(x, dx/dt, t) dt$$
 (1)

over all functions x(t) satisfying the condition that x(0) = c

Let us assume that F satisfies appropriate conditions (which, at the moment, are of no interest to us), so that the minimum is attained for a function satisfying the Euler equation

$$\partial F/\partial x = (d/dt) \, \partial F/\partial x',$$
 (2)

and the additional boundary condition

$$[\partial F/\partial x']_{t=T} = 0 (3)$$

This is a two-point boundary condition, one condition at t=0, one at t=T The difficulty in utilizing conditions of this type is a consequence of the fact that the Euler equation is a second-order differential equation of the form

$$x'' = G(x', x, t), \tag{4}$$

in general, nonlinear

In order to integrate this equation, using either an analog device or a digital computer, we require x(0) and x'(0), or x(T) and x'(T). In a situation such as the above, we must take x'(0) as an unknown and choose it so as to satisfy (3). If the solution is not unique, further difficulties arise

This is a time-consuming process that is not very satisfactory Multidimensional problems of similar type become increasingly more difficult when approached in this fashion

B. Constraints

In the treatment of allocation processes of continuous type, we encounter variational problems of the following type Maximize

$$J(y) = \int_0^T F(x,y) dt, \qquad (5)$$

where

$$dx/dt = G(x,y),$$
 $x(0) = c,$ (6a)

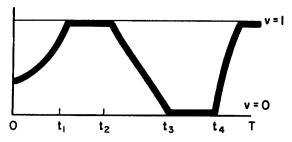

$$0 \le y \le x \tag{6b}$$

The essential feature of novelty is the constraint of (6b)

In order to appreciate the complication that this innocent-looking expression causes, let us recall that the Euler equation of (6a) is valid only when unrestricted variations are allowable, which is to say when 0 < y < x

If, however, y=0 or y=x, then only one-sided variations are permissible In place of Euler equations, we obtain Euler inequalities.

This, alone, is not the principal obstacle. In order to illustrate this graphically, let us set y=vx so that the constraint becomes $0 \le v \le 1$. The graph of v as a function of t can have the following form

The problem is to determine the number of segments and the points of transition t_1 , t_2 , This is an extremely difficult problem that up to the present time has not been resolved in the general case. Under special assumptions concerning F and G, it can be resolved completely (see ref. 12)

Whatever the difficulties arising in this treatment of one-dimensional problems with constraints, they are immeasurably compounded in corresponding multi-dimensional problems

Although there has been some discussion of existence and uniqueness of solution in the literature, very little effort has been devoted to the problem of determining the structure of the solution (see ref 23)

C Linearity

In the first problem above, we discussed some of the difficulties arising from the Euler equation subject to a two-point boundary condition, while the second problem was devoted to the intricacies of combinations of Euler equations and constraints

Let us now consider a variational problem in which no Euler equation exists. Problems of this type, involving linear functionals subject to linear constraints, arise in the study of 'bottleneck processes' (see refs. 5 and 11)

The variational problem is that of determining the maximum of

$$J(y) = \int_0^T F(x,a) \ dG(t), \tag{7}$$

where

$$dx/dt = Ax + By, x(0) = c (8a)$$

$$Cy \le Dx$$
 (8b)

Here x, y, c and a are n-dimensional vectors, while A, B, C, and D are matrices. The inequality in (8b) is to be interpreted component-wise, and (x, a) is the usual inner product

Problems of this type have not been treated in the standard works in the calculus of variations

D. Nonanalyticity

In order to write an Euler equation, we must assume the existence of partial derivatives of the functions that enter—In a number of interesting cases, however, we encounter functions that are only piece-wise differentiable, with the location of the singularities dependent upon the nature of the solution

One example occurs in the study of 'bottleneck' processes. Here a typical problem is that of determining the maximum of

$$J(f,g) = \int_0^T \operatorname{Min}(x,y) \, dt, \tag{9}$$

where

$$\frac{dx/dt = a_1x + a_2y + f, \quad x(0) = c_1,}{dy/dt = b_1x + b_2y + g, \quad y(0) = c_2}$$

$$\int_0^T f dt \le m_1, \quad (0 \le f \le r_1)$$

$$\int_0^T g dt \le m_2 \quad (0 \le g \le r_2)$$
(10a)

Another example of a nonanalytic functional occurs in the study of control processes A typical problem is that of determining the minimum of

$$J(f) = \int_{0}^{T} |1 - u| dt, \tag{11}$$

where

$$d^2u/dt^2+u=f(t), u(0)=0, u'(0)=1,$$
 (12a)

$$-1 \le f(t) \le 1$$
, for $0 \le t \le T$ (12b)

For a study of similar problems, see ref 13

RESUME

From the above examples, we see that the following aspects of variational problems cause grief

- (a) Two-point boundary conditions,
- (b) Constraints,
- (c) Linearity,
- (d) Nonanalyticity

Finally, let us note a point we have repeatedly stressed before—In most mathematical research pertaining to the physical world, we are not so much interested in the solution of a particular problem as we are interested in the solution of a class of problems generated by allowing certain parameters to vary over prescribed ranges—In other words, a 'sensitivity analysis' is vital

What we want then is a uniform method that avoids or overcomes the inconveniences listed above, and permits a sensitivity analysis to be readily performed.

As we shall show, the theory of dynamic programming, to an extent which we shall indicate below, supplies this method

DYNAMIC PROGRAMMING

In order to keep the paper self-contained, let us digress for a moment and sketch the basic features of the theory of dynamic programming We shall restrict ourselves to deterministic processes, since in the applications below all the equations may be considered to arise from processes of this nature

Consider a physical system S whose state at any time is specified by the state vector At each of a certain number of times, specified in advance, or determined by the process, decisions must be made A decision is equivalent to a transformation which converts p into a new state vector p_1 Let us write

$$p_1 = T(p,q), \tag{13}$$

where q is the choice variable specifying the transformation

This process is now repeated, yielding a sequence of state vectors,

$$p_2 = T(p_1, q_1),$$

$$p_N = T(p_{N-1}, q_{N-1})$$
(14)

If N is finite, we speak of an N-stage decision process, otherwise we refer to the process as unbounded or infinite. Although processes of this latter type are physically unrealizable, they are very useful as mathematical models yielding approximate solutions.

Let $\phi(p)$ be a preassigned scalar function of p, and suppose that the purpose of an N-stage process is to maximize $\phi(p_N)$ Let us agree to refer to any admissible choice of (q,q_1, q_{N-1}) as a policy, and one that maximizes as an optimal policy

Observe that the maximum value of $\phi(p_N)$, which we shall assume is actually attained, depends only upon the initial state p and the number of stages in the process

Let us then define

$$f_N(p) = \text{Max}_{[q \ q_1} \quad q_{N-1}] \phi(p_N)$$
 (15)

In order to obtain a recurrence relation for $f_N(p)$, a relation that will be the basis of the computational schemes we shall describe below, we require the following intuitive

PRINCIPLE OF OPTIMALITY An optimal policy has the property that whatever the initial state and initial decisions are, the remaining decisions must constitute an optimal policy with regard to the state resulting from the first decision

The mathematical translation of this statement is the recurrence relation

$$f_{N+1}(p) = \operatorname{Max}_{q} f_{N}[T(p, q)], \qquad N \ge 1,$$

$$f_{1}(p) = \operatorname{Max}_{q} \phi[T(p, q)]$$
(16)

with

In processes in which each decision results in a certain return, and the purpose of the process is to maximize the over-all return, this relation takes the form

$$f_{N+1}(p) = \text{Max}_{q} \{ r(p, q) + f_{N}[T(p, q)] \}$$
 (17)

THE CALCULUS OF VARIATIONS AS A DYNAMIC PROGRAMMING PROCESS

Let us now discuss the application of these ideas to the numerical solution of variational problems

There are two routes we can follow One is intertwined with the continuous nature of the original variational process, while the other employs a discrete approximation to the original process

The first method is primarily useful if we are actually trying to determine the analytic structure of the solution, while the second method is most useful if we are interested in computing the solution numerically Consequently, we shall refer the interested reader to other papers^[2-4-10] for the first method and proceed directly to the discussion of the second method

Let us take the interval [0, T] and divide it into N sub-intervals of length Δ ,

In place of functions x(t) and y(t) defined over [0, T], we shall consider sequences $\{x_k\}$ and $\{y_k\}$ where $x_k = x(k\Delta)$, $y_k = y(k\Delta)$. In place of an integral such as $\int_0^T F(x,y)dt$, we shall consider a sum $\sum_{k=0}^{N-1} F(x_k,y_k)\Delta$. In this way, we reduce problems in the calculus of variations to problems in calculus, involving the variation of functions of N variables

As we shall see, these problems are particularly well adapted to the functional equation technique of dynamic programming

APPLICATIONS

LET US NOW consider the application of these ideas to the problems we discussed in the section "Representative Problems" We shall begin with the second example, since the first requires a slight modification that we discuss below

B. Consistent with the above discretization, the problem we consider

is Maximize

$$J\{y_k\} = \sum_{k=0}^{N-1} F(x_k, y_k) \ \Delta, \tag{18}$$

over all sequences $\{y_k\}$ satisfying the conditions

$$x_{k+1} = x_k + \Delta G(x_k, y_k), \quad (k = 0, 1, 2, \dots, N-1)$$

 $x_0 = c,$ (19a)

$$0 \le y_k \le x_k \tag{19b}$$

Let us assume that F(x,y) and G(x,y) are continuous functions of x and y for all x and y. The maximum is then assumed and we may set

$$f_N(c) = \text{Max } J\{y_k\} \quad (N=0, 1, 2,) \quad (20)$$

It is clear that we have

$$f_0(c) = \operatorname{Max}_{0 \le y \le c} F(c, y) \Delta \tag{21}$$

Employing the principle of optimality, stated in the "Résumé," we obtain the recurrence relation

$$f_{N+1}(c) = \text{Max}_{0 \le y \le c} \{ F(c,y) \Delta + f_N[c + \Delta G(c,y)] \},$$
 (22)

for $N \ge 0$

The determination of each element of the sequence $\{f_N(c)\}$ requires the solution of a one-dimensional maximization problem. At worst, this is a simple process, performed by the usual search method. Under special assumptions concerning F and G, such as convexity or concavity, we can employ superior search methods based upon additional information concerning the nature of the optimal policy [19]

It is important to emphasize two points. No differential properties of F or G are required, a useful fact if these functions are merely given graphically, as they are in many cases. Secondly, the constraint, $0 \le y \le c$, which so complicates the application of the classical techniques, actually simplifies the computation in (22) since it narrows the range of the admissible values of y

In problems of the above type, it is usually better to set y=vx, and allow the variable v to be the independent variable. The range for v is now fixed, $0 \le v \le 1$, which simplifies the programming of the problem

A. Let us now return to a discussion of the first problem We consider it in the following form Maximize over all sequences $\{y_k\}$

$$J\{y_k\} = \sum_{k=0}^{N-1} F(x_k, y_k, k), \tag{23}$$

under the conditions

$$x_{k+1} = x_k + y_k \Delta, \qquad x_0 = c \tag{24}$$

With no loss of generality, we can absorb the factor Δ into F

The dependence of the function F(x,y,t) upon t introduces a third state variable, the time at which the process begins, in addition to the initial 'resource' c and the duration of the process N. In order to reduce the dimensionality of the problem, for both analytic and computational purposes, we keep N fixed and determine the state of the process by means of the starting point and the value of the 'resource' at that time

Consequently, we define

$$f_a(c) = \text{Max} \sum_{k=a}^{N-1} F(x_k, y_k, k)$$
 (25)

for a=0, 1, 2, N-1 We have

$$f_{N-1}(c) = \text{Max}_{\nu} F(c, y, N-1),$$
 (26)

and, generally,
$$f_a(c) = \operatorname{Max}_y \left[F(c, y, a) + f_{a+1}(c + y\Delta) \right]$$
 (27)

for a=0, 1, 2, N=2

It is interesting to observe that in some cases it will be sufficient to tabulate the functions $f_a(c)$, rather than the functions $f_a(c)$ themselves Regarding (27), the maximizing y is determined by the equation

$$\partial F/\partial y + \Delta f'_{a+1}(c+y\Delta) = 0$$
 (28)

We see that the maximizing y is determined by a knowledge of $f_{a+1}(c)$ For this value of y, we have

$$f_a(c) = F(c, y, a) + f_{a+1}(c+y\Delta)$$
 (29)

Differentiating with respect to c, we obtain

$$f_{a'}(c) = \partial F/\partial c + f'_{a+1}(c) + (\partial y/\partial c) \left[\partial F/\partial y + \Delta f'_{a+1}(c+y\Delta) \right]$$
$$= \partial F/\partial c + f'_{a+1}(c)$$
(30)

The interpretation of this equation and the connection between the members of the sequence $\{f_a'(c)\}$ and Lagrange multipliers will be discussed elsewhere

Further discussion of variational problems of this type by these methods is contained in references 1, 2, 5, 6, and 10

C. Let us now consider a problem in which no Euler equation occurs Questions of this type arise in the study of bottleneck processes [5, 11]

Consider the following variational problem We wish to maximize the linear form

$$L(x) = \sum_{k=0}^{N-1} [a, x(k)], \tag{31}$$

where x(k) satisfies the vector recurrence relation

$$x(k+1) = Ax(k) + By(k), x(0) = c,$$
 (32)

and y(k), the independent variable, satisfies the constraint

$$C y(k) \le D x(k), \tag{33a}$$

$$y(k) \le 0 \tag{33b}$$

If we wish, we may consider this as a linear programming problem, involving the maximization of a linear form subject to linear constraints. However, a count of variables shows that if x and y are k-dimensional, and there are N stages, we have a problem of Nk dimensions. For example, k=4 and N=30 yields 120, a number commanding a certain respect even

with present-day techniques and machines, particularly if we throw in a few hundred constraints arising from (33a)

It follows that we want to employ a method that utilizes the structure of the decision process so as to reduce the dimension of the problem to its natural level, in this case, four *

We assume, naturally, that the constraints in (33) are such as will yield an actual finite maximum. In problems of this type arising naturally from physical applications, the constraints will automatically be of this nature.

Let us write
$$f_N(c) = \text{Max } L(x)$$
 (34)

Then
$$f_N(c) = \text{Max}_{\{y\}}[(a,c) + f_{N-1}(Ac + By)],$$
 (35)

where the maximum is taken over the region

$$Cy \leq Dc$$
, (36a)

$$y \ge 0$$
 (36b)

For the case of general functions, maximization over a k-dimensional region such as that described in (36) would be an onerous task. However, since we are dealing with linear functions, we know that the maximum is attained at one of the vertices of this region—explaining, incidentally, why differentiation is of no avail here

Since these vertices can be computed quite easily, the determination of a maximum reduces to the testing of a small number of possible values

If y and c are two-, three-, or four-dimensional problems, these problems can be resolved analytically $^{[5\ 10\ 11]}$

D. Let us consider the second problem, in discrete form To begin with, we write the second-order differential equation in the following form

$$du/dt = v,$$
 $u(0) = c_1,$ $dv/dt = -u + f,$ $v(0) = c_2,$ (37)

taking general boundary conditions This system of equations is now converted into a difference system, †

$$u_{k+1} = u_k + \Delta v_k,$$
 $u_0 = c_1,$ $v_{k+1} = v_k + \Delta (g_k - u_k),$ $v_0 = c_2$ (38)

The problem we wish to consider is that of minimizing

- * We can take advantage of homogeneity and reduce this to three, an important point in view of the relatively limited memory of current machines
- † This is actually not a satisfactory scheme because of stability difficulties. These may be overcome, but a discussion of them would take us too far afield

$$S_N = \sum_{i=0}^{N-1} |1 - u_k|, \tag{39}$$

over all sequences $\{g_k\}$ subject to the condition that $-1 \le g_k \le 1$ As in the preceding sections, set

$$\min S_N = f_N(c_1, c_2), \tag{40}$$

with

$$f_0(c_1, c_2) = |1 - c_1| \tag{41}$$

Then

$$f_{N+1}(c_1,c_2) = \operatorname{Min}_{-1 \le g_0 \le 1} \{ |1-c_1| + f_N[c_1 + \Delta c_2, c_2 + \Delta(g_0 - c_1)] \}$$
 (42)

Further details concerning processes of this type may be found in refs 6, and 7 Related problems, treated by other methods, are discussed in refs 13, 14, and 12

CONTROL PROCESSES

The above is a particular example of a 'control process' of the type that might be encountered in mechanical or electrical engineering. A general discussion of the application of the theory of dynamic programming to these processes will be found in a paper presented before a symposium on nonlinear control processes at Brooklyn Polytechnic Institute in April, 1956

DEGREE OF APPROXIMATION AND CONVERGENCE

A question that immediately arises in connection with the above method is that of the degree of approximation of the solution of the discrete problem to the continuous problem, and, as a special case, the convergence of the discrete process to the continuous process as $\Delta \rightarrow 0$

These are difficult problems, which in any application are usually treated by computing the solution for a range of values of Δ , say Δ , $\frac{1}{2}\Delta$, and 2Δ , and comparing the answers—If they are close, we retain this particular value of Δ —If the answers are quite different, we decrease Δ still further

A certain amount of theoretical work has been devoted to these questions, [8 18 20 22] but much remains to be done, particularly in connection with the important problem of determining efficient computational procedures

ON THE PHILOSOPHY OF MODEL-BUILDING

In this penultimate section we should like to stress one advantage of the approach illustrated above over numerical approaches which are directed toward the numerical solution of one particular variational problem

Observe that what we have constantly done in treating the variational problems occurring in the above sections is to imbed the individual problem within a family of problems of the same type — The individual problem is solved, incidentally, in the course of solving the general problem

In many cases this is the only feasible method of tackling the particular problem, in other cases there are available other methods that may solve the original problem in a shorter time. It is natural to ask then what the functional equation method yields that other methods, in general, do not

The answer is precisely—the solution of the general problem

In order to understand why the solution of the general problem is of significance, we must intersperse a few words concerning the philosophy of model-building

In the first place, there is general agreement concerning the fact that no mathematical model, no matter how sophisticated, can represent reality. It merely represents an approximation of greater or lesser validity. Add to this fact the inherent uncertainty of the future—an almost tautological definition of the future, since the past may be defined as that which is known and the future as that which is unknown—and serious doubts arise as to the worth of mathematical models.

A response to these doubts lies in the concept of a 'sensitivity analysis,' or in purely mathematical parlance, a 'stability' investigation. In the majority of cases, when we are investigating physical or mathematical phenomena, we are not so much interested in a particular solution as we are in the dependence of the solution upon the parameters describing the phenomena. For example, we are interested in the dependence of the solution upon the initial resources and the duration of the process

In other terms, in the main, we are more interested in the structure of policies than we are in numerical solutions. If we can discern a uniform structure common to a number of approximations, of increasing degree of complexity, to a specific process, then we can feel that we have derived something of value from our mathematical abstraction.

There are a number of problems occurring in applications in which it is sufficient to determine a numerical answer once and for all, and then use this answer over and over. The multiplication table is a specific example of this

As a rule, however, we may expect all fields to become progressively more complicated as that elusive will-o-wisp 'reality' is tracked down. As this happens, the structure of policies will assume the central role as the prime object of research.

FINITE DIMENSIONAL VARIATIONAL PROBLEMS

We have restricted ourselves here to a discussion of variational problems arising from the calculus of variations. The same methods are also applicable to a number of finite-dimensional problems not readily treated by the conventional methods of calculus. The interested reader may consult refs. 1 2 6 and 9
